The Global Boundary Stratotype and Section Point (GSSP) for the base of the Santonian Stage, “Cantera de Margas”, Olazagutia, northern Spain

The GSSP for the base of the Santonian Stage is defined at 94.4 m in the eastern border of the “Cantera de Margas” quarry, Olazagutia (Navarra, N. Spain: 42°52’05.3” N, 2°11’40” W) and marked by the first occurrence (FO) of the inoceramid bivalve Platyceramus undulatoplicatus. This first occurrence is located about 9 m below the contact between a lower marly unit and an upper more calcareous unit. The FO of the planktonic foraminifer Sigalia carpatica is the secondary marker of the GSSP and first occurs 7 m below the primary marker, but it becomes consistently present about 4.2 m above the boundary. In addition, six peaks in the carbon stable isotope curve can be recognized between the Kingsdown Event 17.2 m below and the Bedwell Event 12.35 m above the GSSP. The basal Santonian GSSP was approved by the International Subcommission on Cretaceous Stratigraphy in September 2010, by the International Commission of Stratigraphy in April 2012, and ratified by the International Union of Geological Sciences in January 2013.

Introduction

The Santonian Stage was proposed by Coquand (1857), presumably named after the town of Saintes in south-west France. One of the localities mentioned by Coquand was Javrezac, a village on the north-west side of Cognac. The boundary there was drawn on a hardground between glauconitic, nodular limestone, with many Exogyra of the Coniacian below, and soft micaceous chalk of the Santonian above.

At the First Symposium on Cretaceous Stage Boundaries (Birkelund et al. 1984) the consensus was that the first occurrences (FO) of the ammonite subgenus Texanites (Texanites) and of the inoceramid bivalve Cladoceramus (=Platyceramus) undulatoplicatus (Roemer) were the two best boundary criteria. Texanites (Texanites) had been used over a wide area, although in classic regions of north-west Europe this subgenus is far too rare to be a practical marker (Hancock, 1991). Platyceramus undulatoplicatus is widespread and on account of its characteristic form and sculpture, is easy to identify. In N. Africa Platyceramus siccensis (Pervinquière) is associated with Texanites, and was considered another possible marker for the base of the Santonian.

In the Santonian Working Group report to the second Symposium on Cretaceous Stage Boundaries (Lamolda and Hancock, 1996) the FO of Platyceramus undulatoplicatus was confirmed as the primary marker for the base of the Santonian Stage. The FO of Texanites (Texanites) was rejected because it occurs below the lowest Platyceramus undulatoplicatus and had been cited in assemblages with inoceramids normally regarded as Coniacian (Lamolda and Hancock 1996). The FO of the planktonic foraminifer Sigalia carpatica was accepted as a secondary marker for the basal Santonian. It is widespread in the Mediterranean region of the Tethys, is associated with Inoceramus siccensis and Texanites in Tunisia, and in northern Spain (Navarra) its FO is very close to the lowest occurrence of Platyceramus undulatoplicatus. Three sections were approved as candidate GSSPs; Olazagutia Quarry (Navarra, Spain), Seaford Head (Sussex, England) and Ten Mile Creek (Dallas, Texas).

Results were published in a special issue of Cretaceous Research “Stratigraphy of the Coniacian–Santonian transition” (vol. 28 no. 1, 2007; Gallefmi et al., Howe et al., Lamolda and Paul, Lamolda et al., Peryt and Lamolda), and another paper in Acta Geologica Polonica (Gale et al., 2007). The Olazagutia section was chosen as the GSSP by the Santonian Working Group in November 2007 and approved by the International Subcommission on Cretaceous Stratigraphy in September 2010. This decision was finally approved by the International Commission of Stratigraphy in April 2012, and ratified by the International Union of Geological Sciences in January 2013.

The “Cantera de Margas” Section

The Olazagutia section is located in the Basque-Cantabrian Region (BCR) of northern Spain, to the west of the Pyrenees (Fig. 1). During the Late Cretaceous the area around Olazagutia was a distal part of the Navarro-Cantabrian Platform, except in the Maastrichtian when a proximal ramp with shallow-water facies was established. The platform is subdivided by both longitudinal (NW-SE) and transverse (NE-SW) faults. In spite of local and/or temporary fluctuations, the platform remained typically an outer shelf environment where deposits
Episodes Vol. 37, no. 1

are mainly fine pelitic sediments (Amiot et al., 1983; Wiedmann et al., 1983; Gallemí et al., 2007).

In the area studied both the Coniacian and Santonian consist of intercalated marls and marly limestones. The thickness of Coniacian strata is estimated to be 400-600 m (Ramírez del Pozo, 1971; Zander, 1988). Kannenberg (1985) estimated the thickness of the Santonian strata in the “Cantera de Margas” at Olazagutia to be about 230 m.

The section is located in a working quarry to the south of Olazagutia, Navarra, Spain (Fig. 1). Its geographical location is 42º 52' 05.3" N, 2º 11' 40" W; Lambert Coordinates 919, 722, 1:25000 topographic sheet no. 113-4 Olazagutia.

Further details on the general stratigraphy around Olazagutia are given by Küchler (2002). A general overview of Upper Cretaceous sequence stratigraphy of the BCR was given by Gräfe and Wiedmann (1998), who defined the boundary between cycles UC11 and UC12 above, but close to, the current Coniacian/Santonian boundary (CSB).

Lithostratigraphy

The section along the disused eastern side of the Cantera de Margas quarry exposes ca. 160 m of marls and marly limestones and extends from the middle Coniacian to the middle Santonian. The lower, more marly part is referred to the La Barranca Member of the El Zadorra Formation; the higher part to the Olazagutia Formation (Fig. 2), as defined by Amiot (1982). A part of the section has been studied in more detail, on a ramp into the middle level of the quarry, and belongs to the lower part of the Olazagutia Formation (Figs. 3-5).

Thin (10-20 cm) limestone beds occur from ca. 20 m below to 9 m above the Coniacian/Santonian boundary (as defined by the FO of *P. undulatoplicatus*), which occurs at 94.4 m above the base of the section (Fig. 4). Higher up, more uniform and thicker-bedded limestones occur. Marcasite nodules, often rusty-weathered, occur from ca. 7-14 m above the boundary. There are also very weak hints of at least five larger-scale cycles ca. 10 m thick, each starting with rather thicker chalk beds in the boundary interval that we studied. The base of the lowest cycle lies in the covered interval below our section and has been used to define the boundary between the Zadorra and Olazagutia formations (Amiot, 1982).

Macrofossils are sufficiently common in parts of the section to contribute to the lithological characteristics of the beds. They are rare at the base of the section, but echinoids and inoceramid bivalves occur sporadically in the first 75 m or so. Echinoids are particularly abundant in the 12 m below the boundary, and are fairly common up to at least 20 m above it (Fig. 3). Inoceramids, especially *P. undulatoplicatus*, appear abundantly at the boundary (Fig. 3). *Platyceramus undulatoplicatus* is very common in the first 2 m, is then sporadic for nearly 10 m, with its higher occurrence about 11.5 m above the boundary. Sponges (sometimes iron-rich and rusty-weathered) occur both sporadically and in distinct sponge-rich beds from 2.5 m below to 15 m above the boundary (Fig. 3).

**Biostratigraphy**

Inoceramids, planktonic foraminifera and calcareous nanofossils can be used to define biostratigraphic zones across the boundary
Figure 2. The Olazagutia section, with indication of main first and last occurrences (FO and LO) of inoceramid, echinoid and ammonite taxa (after Gallemí et al., 2007, fig. 5).
Inoceramid bivalves

Inoceramids occur discontinuously, although they are abundant in the upper half of the section. The first examples of *Magadiceramus* occur at 64.6 m, ca. 11 m below the base of our studied section, and indicate the presence of the *M. subquadratus* Zone of late Coniacian age. *Platyceramus undulatoplicatus* first appears at 94.4 m and defines both the base of the eponymous zone and the Santonian Stage (Fig. 3). It occurs through a total range of 11.5 m. Almost certainly, the lowermost and uppermost levels correspond to inoceramid events 1 and 2 of the Kent coast in England (Jenkyns et al., 1994; Jarvis et al., 2006). Both the FO and LO are reliable bioevents, that is, they plot very close to the best fit lines in graphic correlation between all pairs of sections so far investigated (Paul and Lamolda 2009). *Platyceramus cycloides* subsp. and *Coridiceramus* spp. are commonly recorded in the lower part of the Santonian. Details of macrofossils recorded at Olazagutia are given in Fig. 2 (after Gallemi et al., 2007).

Planktonic Foraminifera

The main planktonic taxa belong to keeled, trochospiral species of genera such as *Contusotruncana*, *Dicarinella*, *Globotruncanina* and *Marginotruncanina*. The most abundant components are biconvex species of *Marginotruncanina*. Planktonic foraminiferal assemblages found in the samples studied enable recognition of biozonations based on globotruncanids and heterohelicids (Fig. 6). *Dicarinella asymetrica* (Sigal) occurs throughout the section studied (Lamolda et al., 2007), which thereby belongs entirely to the *Dicarinella asymetrica* Zone. Heterohelicid species are also useful for biozonation. The first occurrence of *Sigalia carpathica* Salaj and Samuel is located ca. 7 m below the first occurrence of *Platyceramus undulatoplicatus*, and is used to characterize the lower boundary of the eponymous biozone, following Nederbragt’s (1990) biozonation. The underlying sediments belong to the *Pseudotextularia nuttalli* Zone. More details on planktonic foraminifera are given in Lamolda et al. (2007), and below under the overview of main fossil groups.

Nannofossils

Melinte and Lamolda (2002) studied nannofloral assemblages, which belong to nannofossil zones CC15-CC16 of Sissingh (1977), and calcareous nannofossil zones UC10-UC12 of Burnett (1998), respectively (Fig. 7). A succession of bioevents characterizes the CSB interval in the section studied (Fig. 3). Of special note is the local first occurrence of *Lucianorhabdus inflatus* Perch-Nielsen and Feinberg.
which is very close to the base of the Santonian (1.75 m below), as in
the Romanian Carpathians (Melinte and Lamolda, 2007). Other
nannofossil events observed in the succession at Olazagutia are high
abundances of *Lucianor habdus* spp. and *Micula concava* (Stradner)
Verbeek in the CSB interval, followed by the increasing abundance
of *Calculites* within the lowermost Santonian (Melinte and Lamolda,
2002). Further comments are given below. Illustrations of the
calcareous nannofossils mentioned can be found in Lamolda et al.

**Stable Isotopes**

Carbon isotope values across the Coniacian/Santonian boundary
only vary by a maximum of 0.37‰ (Fig. 8). There is no major
excursion, such as occurs across the Cenomanian/Turonian boundary.
Nevertheless, they do show a gradual and continuous decline through
the sampled interval from a maximum of +3.05‰ (sample 2) to
+2.68‰ (sample 45), with some fluctuations (Fig. 8). In particular,
there is a relatively large drop from 2.98 to 2.71‰ over four samples
just below the first appearance of *P. undulatoplicatus*. Above this level values increase again to 2.91‰ over the
next four samples.

Results from Olazagutia were originally compared
(Lamolda and Paul, 2007) with the carbon isotope curve of
Jenkyns et al. (1994) for east Kent (Fig. 8) and later
(Paul and Lamolda 2009) with the carbon isotope curves
of Jarvis et al. (2006) for southern England (Fig. 9), since
the first and last occurrences (FO and LO) of *P. undulatoplicatus*
are recorded in both places. We used the total ranges of *P. undulatoplicatus* to estimate relative
sedimentation rates at both localities and adjusted the
scales of the sections accordingly to produce our
correlation (Fig. 9). Both carbon isotope curves lack major
excursions, but do show similar features. In both, carbon
isotope values decline across the Coniacian/Santonian
boundary, with one or two brief reversals. In particular,
three minima (the late Coniacian, at the boundary, and in
the early Santonian) can be recognized in both curves.

Using the total thickness of the Coniacian and
Santonian in east Kent (Jenkyns et al., 1994, fig. 13), the
time scale of Harland et al. (1989) and our best correlation
(Fig. 9), Paul and Lamolda (2009) estimated that the mean
sampling interval at Olazagutia was approximately 22,000
years. Within the limits of our sampling, $\delta^{13}$C curves and
the total range of *P. undulatoplicatus* gave equally accurate
correlations (Paul and Lamolda 2009). This, in turn,
confirms that the first occurrence of *P. undulatoplicatus*
is a very good primary marker for the Coniacian/Santonian
boundary, at least in western Europe. Further comments
are given below in an overview of carbon stable isotopes.

**Palaeobiogeography**

Palaeogeographic reconstructions of the region
around the CSB provide a 30º N palaeolatitude for
northern Spain (around 42º N at present). This part of
the northern Tethys had direct communications with the North
Atlantic to the west, and the London-Paris basin to the
north. It was part of the palaeotropics but with influences
of the northern temperate regions.

Most of the nannofossils occurring around the CSB interval herein
are cosmopolitan taxa, although a small number of them are more
closely related to low- than to high latitudes. A significant component
of the nannofloras from the Olazagutia section is *Watznaueria barnesae*,
the most abundant Cretaceous cosmopolitan nannofossil.
Concerning this taxon, Thierstein (1981) indicated that it showed
a latitudinal distribution pattern, being more common at low latitudes,
becoming less abundant towards higher latitudes, although still
forming an important component of high-latitude nannofloral
assemblages. The presence of the nannofossils *Lithastrinus grillii*
and *Lithastrinus septenarius*, both identified in the Olazagutia section,
indicates, according to Valori (1992), warm to temperate waters of
low-mid latitudes. Another important component of the assemblages
identified in the studied section is the genus *Nannoconus*,
which reached, at certain levels, >15% of the nannofloral assemblage.
Interestingly, the abundance of nannoconids sharply decreases below
the Coniacian/Santonian boundary, almost coincident with a minimum
in the $\delta^{13}$C curve. It is noteworthy that the Upper Cretaceous

![Figure 4. A general view of the Cantera de Margas section. The approximate location of the Coniacian/Santonian boundary is shown by the white line.](image1)

![Figure 5. The Coniacian/Santonian transition at the Cantera de Margas section. The level of the FO of *P. undulatoplicatus* is marked by the white line.](image2)
nannoconids are also believed to be indicative of low-middle latitudes, rather than high ones. In contrast, Kamptnerius magnificus and Gartnerago segmentatum, nannofossils recorded infrequently and discontinuously in our samples, and mainly restricted to Olazagutia in the lowermost Santonian, are usually common to abundant at high latitudes (Thierstein, 1976; Sylva, 1995) cited K. magnificus as cold-water species too. It is present in the Tethyan Realm but infrequently. The δ18O curve shows higher values in the lowermost Santonian at Olazagutia, overlying a decreasing trend in the uppermost Coniacian and CSB, which is consistent with occurrences of the species cited from temperate regions, mainly at the same levels. This could reflect global climatic changes or a more local effect involving the balance between Tethyan and Atlantic water sources (Lamolda and Paul, 2007). Also noteworthy is the high abundance of holococcoliths in the section studied. These taxa are believed to be more abundant in the nannofossil assemblages, and they are often related to cold-water incursions into lower latitudes (Melinte, 1999). The δ18O curve shows higher values in the lowermost Santonian at Olazagutia, overlying a decreasing trend in the uppermost Coniacian and CSB, which is consistent with occurrences of the species cited from temperate regions, mainly at the same levels. This could reflect global climatic changes or a more local effect involving the balance between Tethyan and Atlantic water sources (Lamolda and Paul, 2007). Also noteworthy is the high abundance of holococcoliths in the section studied. These taxa are believed to be more abundant in the...
nearshore and epicontinental areas than in open oceans (Thierstein, 1976; Perch-Nielsen, 1985). This observation is consistent with the palaeogeographical setting of the Olazagutia section, situated in the Navarro-Cantabrian Platform, with sediments deposited on a rapidly sinking shelf.

Planktonic foraminiferal assemblages are typical of the Tethyan Realm, mostly of globotruncanids s.l., whereas globigeriniforms (e.g., *Archaeoglobigerina*) are usually minor components. The genus *Sigalia* occurs, especially *S. carpatica*, which characterizes the palaeotropics between the Atlantic and southern Tibet. Interestingly, the occurrence of benthic foraminifera, mainly *Neoflabellina* and *Stensioeina*, allows a correlation with the temperate northern region, especially in the CSB interval.

The inoceramid fauna belongs to the southern Euroamerican Province (Kaufman, 1973). In fact, the upper part of the Coniacian in northern Spain, including the southern central Pyrenees, is characterized by a *Magadiceramus* spp. fauna, and the lowermost Santonian by *P. undulatoplicatus*. No sphenoceramids are known in the region.

In summary, most of the fauna and calcareous nannofossils are cosmopolitan or with a wide palaeogeographic distribution in low and middle latitudes. It is noteworthy that some planktonic foraminifera (e.g., *Globotruncana, Costellaginera*), and benthic foraminifera (e.g., *Neoflabellina, Stensioeina*) enable correlation with northern temperate and austral regions.

### Access

The owners of the quarry, Cementos Portland, have agreed to maintain the section and allow access for research (Fig. 1). The GSSP is protected by governmental agreement between the Navarran Regional Government, the Instituto Geológico y Minero de España (Spanish Geological Survey) and the owners.

### Overview and discussion of the main fossil groups and events

#### Inoceramids

The geographic distribution of inoceramid species relevant for the CSB highlights a bioprovinciality in their assemblages. The primary marker *Platyceramus undulatoplicatus* (Fig. 10) has a wide geographic distribution, but it is not known in the Boreal, nor in the

---

**Figure 7.** Range-chart of nannofossil species in the Olazagutia section. Abundances were recorded as follows: abundant, >1 specimen/field of view (FOV); common, 1 specimen/2-10 FOV; few, 1 specimen/11-20 FOV; rare, 1 specimen/>20 FOV (after Melinte and Lamolda, 2002, fig. 2).
Pacific realms. The FOs of *Platyceramus cycloides* and subspecies seem to be good proxies for the CSB, in the absence of *P. undulatoplicatus*. They occur in North Africa, where they used to be the marker for the local CSB. They co-occur with *P. undulatoplicatus* in Ten Mile Creek, northern Spain (Gale et al. 2007, Galleni et al. 2007), northern Germany (López et al., 1992), and Austria (Tröger and Summesberger, 1994). The LO of *Magadiceramus* spp. is not a good proxy for the CSB, as it has been recorded well below the FO of *P. undulatoplicatus*. The FO of *Cordiceramus cordiformis*, in the lower part of the Santonian, could help in recognizing of the CSB, as this species co-occurs with *P. undulatoplicatus* in northern Spain and at Ten Mile Creek. It is also known from the lower part of the Santonian in Germany. In the Boreal Realm, the FO of the *Volviceramus cardissoides-pachti* group may be a good proxy for the CSB (Tröger 1989).

**Ammonites**

Most ammonite species occurring across the Coniacian/Santonian transition are not cosmopolitan. Nevertheless, they allow a biozonation from the middle Coniacian to the middle Santonian. The LO of the late Coniacian species *Protexanites bourgeoisi*, which has a wide geographical distribution, is not a proxy for the CSB as its known records lie well below the FO of *P. undulatoplicatus*. Several species of *Hemitissotia* have their LOs close to and above the FO of *P. undulatoplicatus* in northern Spain, and they could thus be a proxy for the CSB, but of local interest only. The FO of *Kitchinite emscheris* may be a good proxy for the CSB, but exclusively in the Münsterland Basin, Germany (Kaplan and Kennedy 2000). The FO of *Placenticeras polyopsis* in the lowermost Santonian was regarded by Dhondt et al. (2007) as a good proxy for the CSB, but checks of other sections are needed to ascertain whether or not it is a reliable marker.

**Planktonic Foraminifera**

*Sigalia carpatica* (Fig. 11A-C), the secondary marker of the CSB (Lamolda and Hancock, 1996), is a relatively widespread taxon in the palaeotropics from the Atlantic Ocean to southern Tibet. Both its
FO and consistent occurrence lie near the CSB, below and above, respectively. The FO of *Costellagerina pilula* (Fig. 11G, H) is just below the CSB and this widespread species may be an additional useful marker.

The FO of pillbox-like morpho-types of *Globotruncana linneiana* (Fig. 11D) is close to the CSB in Europe, both in typical Tethyan and in temperate northern localities. It is a proxy of the CSB to be checked in other regions where neither *P. undulatoplicatus* nor *S. carpatica* are found.

Relatively common occurrences of *D. asymetrica* (Fig. 11F, I) similar to that of *D. concavata*, are known from lowermost Santonian strata at many localities. Nonetheless, it occurs throughout the upper Coniacian at low frequencies. Thus, its first common occurrence may be an additional proxy of the CSB in the palaeotropics, except in shallow-water facies.

**Benthic Foraminifera**

The uppermost Coniacian is characterized by the LO of *Stensioeina granulata*, and the FOs of *S. polonica*, *S. granulata incondita*, *Cibicides eriksdalensis*, and *Neoflabellina gibbera*. In the lowermost Santonian, *S. granulata incondita*, *C. eriksdalensis*, and *N. gibbera* increase their abundances, and the FOs of *Neoflabellina praecursor* and *N. santonica* are recorded. All cited species, except the latter two, have a wide geographical distribution, especially in the

![Figure 10. Platyceramus undulatoplicatus (Roemer), the primary marker for the base of the Santonian Stage. A Universitat Autònoma de Barcelona 67000. Found loose. **Fig. 11. Planktonic foraminifera from the Cantera de Margas GSSP section. A1-A2 – Sigalia caratica Salaj and Samuel, sample 98-5; B1-B2, C1-C2 – Sigalia caratica Salaj and Samuel, sample 97-8; D1-D2 – Globotruncanina lineinea (d’Orbigny), sample 98-10; E1-E2 – Globotruncanina lineinea (d’Orbigny), sample 97-4; F1-F2 – Dicarinella asymetrica (Sigal), sample 97-6; G1-G2 – Costellagerina pilula (Belford), sample 97-6; H1-H2 – Costellagerina pilula (Belford), sample 98-10; I1-I2 – Dicarinella asymetrica (Sigal), sample 98-1. Scale bars represent 100 µm.**
transitional region between the Tethys and Boreal realms. *Neoflabellina* spp. are known from North America (Texas, USA), the Russian Platform, Western Carpathians, Germany, northern Spain and Tunisia. Thus, they are potentially good indices for the CSB in different paleogeographical areas.

**Calcareous Nannoplankton**

The CSB is placed between the FO of *Lucianorhabdus cayeuxii* and the LO of *Lithastrinus septenarius*, within the CC16 Zone of Sissingh (1977), and in the UC11c Subzone of Burnett (1998). Above the FO of *L. cayeuxii* a consistent occurrence of *Calculites obscurus* is noted, which in other localities is recorded as its local FO. Another nannofossil event identified in northern Spain, Austria and southern Romania that could be further checked for its reliability in other sections, is an increase of holococcoliths sometimes associated with the FO of *Lucianorhabdus inflatus*, above the FO of *Lucianorhabdus cayeuxii* and below the CSB. In addition, a reliable event could be a higher abundance of *Micula concava*, which occurs across the CSB.

**Carbon Stable Isotopes**

Carbon stable isotope curves have been published for the two candidate sections for the Coniacian-Santonian boundary GSSP (Gale et al. 2007; Lamolda and Paul 2007). In addition, Jarvis et al. (2006) published several curves covering the same interval for sections in southern England in which they name a series of carbon isotope events. Those isotope events are always local maxima, (i.e., peaks) in the carbon isotope curve, but the intervening minima (troughs) may also be used in correlation (Paul and Lamolda 2009). The correlation of the isotope events in England is further supported by very detailed bio- and lithostratigraphy. Jarvis et al. (2006) listed 45 bioevents and/or stable isotope events allow recognition of the CSB at those localities despite the absence of the primary marker, *P. undulatoplicatus*.

**Cyclostratigraphy and geochronology**

As mentioned above under lithostratigraphy, it appears possible to distinguish about five decametric cycles across the CSB in the Olazagutia section. Whether or not these cycles can be correlated to other localities, e.g., the Niobrara Formation, Western Interior, USA (Locklair and Sageman, 2008) is unknown. Those authors proposed a 400 kyr-cycle series, allowing the identification of both the current and previously accepted local CSB. Although the Western Interior shows an endemic macrofauna, especially ammonites, those results are a good point of reference for further research. According to Gradstein et al. (2012) the CSB is 86.26 ± 0.12/0.49 Ma in age.

**The sequence of events across the Coniacian-Santonian transition in Olazagutia**

The results discussed above enable recognition of the sequence of events across the Coniacian-Santonian transition along the eastern border of the “Cantera de Margas” quarry (Olazagutia). These are, in stratigraphic order from oldest (1) to youngest (20). Potentially reliable events (Paul and Lamolda 2009) are shown bold, other events previously considered relevant are underlined.

20 – The LO of *Lithastrinus septenarius* at the 112.4 m level.
19 – The Bedwell δ 13C stable carbon isotope event at the 106.75 m level.
18 – The LO of *Platyceramus undulatoplicatus* at the 105.9 m level.
17 – The FO of *Platyceramus cycloides* at the 99.1 m level.
16 – The Michel Dean δ 13C stable carbon isotope event and consistent occurrence of *Sigalia carpatica* at the 98.6 m level.
15 – The FO of *Neoflabellina praecursor* and the first common occurrence of *Dicarinella asymetrica* at the 95.8 m level.
14 – The FO of the pillbox-like morphotypes of *Globotruncanina linneiana* at the 94.5 m level.
13 – The FO of *Platyceramus undulatoplicatus* at the 94.4 m level.
12 – The FO of abundant *Micula concava* at the 93.8 m level.
11 – The FOs of *Neoflabellina gibbera* and *Lucianorhabdus inflatus*, and the FO of abundant holococcoliths at the 92.6 m level.
Summary

- The “Cantera de Margas” section has a continuous exposure, along its eastern border, through about 160 m, to the middle Cenomanian to the middle Santonian.
- The GSSP for the base of the Santonian Stage lies at 94.4 m, marked by the first occurrence of the inoceramid *Platyceramus undulatoplicatus*, which occurs through 11.5 m, and is very common in the first 2 m.
- The CSB is bracketed by Peak 3 and the Michel Dean $\delta^{13}C$ stable carbon isotope events, 3.55 m below and 4.4 m above the CSB, respectively. The CSB lies immediately above the $\delta^{13}C$ minimum between these two peaks.
- Graphic correlation of stable carbon isotope events is one of the most accurate tools for international correlation (Paul and Lamolda 2009). It allows calibration of bioevents, plus distinction of which are good time planes and which are not. It should be a standard procedure in selecting GSSPs.
- Only four bioevents appear to be reliable as time planes: both the FO and LO of *P. undulatoplicatus*, the FO of the nannofossil *Lucianorhabdus caerulexxii*, and the FO of the inoceramid *Platyceramus cycloides*. The latter is also a good proxy for the CSB.
- In the critical interval, e.g., between the FO of the planktonic foraminifer *Sigalia carptica*, 7 m below the CSB and the FO of *P. cycloides*, 4.7 m above the CSB, there are 10 additional notable bioevents to characterize the CSB interval. These allow correlation of Olazagutia with northern and southern temperate provinces, in addition to Tethyan localities.

Acknowledgements

We are grateful to the owners, Cementos Portland, for unlimited access to the quarry for research and for the original version of Fig. 1B, showing permitted access. We also thank especially Jaume Galleni, Jana Ion, Gregorio López, Ludmila F. Kopaevich, Ricard Martínez, Mihaela C. Melinte-Dobrinescu, Seiichi Toshimitsu, and Elena Jagt-Yazykova, all of them members of the Santonian Working Group, for their help in preparing the proposal. Reviews by J. W. M. Jagt, H. Nishi and M. Wagenreich significantly improved the initial version of the manuscript.
